**Keywords:** Single-sideband transform; MVDR beamformer; Filter banks; Array signal processing; Signal enhancement.

## 1. Introduction

Beamformers are an important tool for signal enhancement, having a plethora of applications from hearing aids [1] to source localization [2] to imaging [3,4]. Usually, beamforming techniques are used either strictly on the time domain, strictly on the frequency domain, or on the time-frequency domain [5], the later allowing the exploitation of frequency-related information, while being able to adapt over time to changes in the signals under study. In this regard, the most used technique to study a signal on the time-frequency domain is the Short-Time Fourier Transform (STFT). However, different transforms can also be employed, allowing distinct details and data of the examined signals to be acknowledged.

One such transform is the Single-Sideband Transform (SSBT) [6,7], which has the particularity of its frequency domain spectrum being real-valued. It has been shown that the SSBT works particularly well with short analysis windows [6], lending itself to be useful when working with the convolutive transfer function (CTF) model [8] for signal analysis.

When working with beamformers, two of the most important and used requirements are the minimization of noise on the output (noise being any unwanted signal), and the distortionless-ness of the desired signal, in which both are achieved simultaneously when

using a minimum-variance distortionless-response (MVDR) beamformer [9,10]. Since the MVDR beamformer works on the frequency (or in this case, time-frequency) domain without any specification on the transform chosen, it is interesting to explore and compare the performance of this filter, when designing it through different time-frequency transforms.

Motivated by this, in this paper we explore the SSB transform, and its application on the subject of beamforming when dealing with the CTF model. We propose an approach for the CTF that allows us to separate the desired and undesired parts of speech, when one is located in an environment with reverb, and employ this approach for designing the MVDR beamformer. We also explore the limitations and traits of the SSBT, and how to properly adapt the MVDR beamformer to this new transform's constraints.

We organized the paper as follows: in Section 2 we introduce the proposed time-frequency transforms, how they're related and which qualities from each are important; Section 3 presents the signal model considered in the time domain, and how it is transferred into the time-frequency domain within the considered framework; and in Section 4 we develop a true-MVDR beamformer with the SSBT, taking into account its features. In Section 5 we present and discuss the results, comparing the studied methods and beamforming techniques obtained; and finally in Section 6 we conclude this paper.

## 2. STFT and Single-Sideband Transform

When studying signals and systems, often frequency and time-frequency transforms are used in order to change the signal domain [11], allowing the exploitation of different patterns and informations that are inherent to the signal.

Given a time-domain signal  $x[n]$ , its Short-time Fourier Transform (STFT) [12,13] is given by

$$X_{\mathcal{F}}[l, k] = \sum_{n=0}^{K-1} w[n] x[n - l \cdot O] e^{-j2\pi k \frac{(n-l \cdot O)}{K}} \quad (1)$$

where  $w[n]$  is an analysis window of length  $K$ ; and  $O$  is the overlap between windows of the transform, usually  $O = \lfloor K/2 \rfloor$ . Even though the STFT is the most traditionally used time-frequency transform, it isn't the only one available. Therefore, exploring different possibilities for such an operation can lead to interesting results.

The Single-Sideband Transform (SSBT) [6] is one such alternative, in which the frequency values are cleverly used such that its spectrum is real-valued. The SSB transform of  $x[n]$  is defined as

$$X_S[l, k] = \sqrt{2} \Re \left\{ \sum_{n=0}^{L-1} w[n] x[n - l \cdot O] e^{j2\pi k \frac{(n-l \cdot O)}{K} + j\frac{3\pi}{4}} \right\} \quad (2)$$

Assuming that  $x[n]$  is real-valued, one advantage of using the STFT is that we only need to work with  $\lfloor \frac{K+1}{2} \rfloor + 1$  frequency bins, given its complex-conjugate behavior. Meanwhile, the SSBT needs to use all  $K$  possible bins to correctly capture all information of  $x[n]$ , however it is real-valued.

It is possible to define the SSBT using the STFT (assuming all  $K$  bins are available), such that

$$\begin{aligned} X_S[l, k] &= \sqrt{2} \Re \left\{ X_{\mathcal{F}}[l, k] e^{j\frac{3\pi}{4}} \right\} \\ &= -\Re \{ X_{\mathcal{F}}[l, k] \} + \Im \{ X_{\mathcal{F}}[l, k] \} \end{aligned} \quad (3)$$

which will prove itself to be a very useful formulation.

It is possible to show that, unlike with the STFT, the convolution theorem doesn't hold when using the SSBT. That is, if  $y[n] = h[n] * x[n]$ , then  $Y_{\mathcal{F}}[l, k] = H_{\mathcal{F}}[l, k] * X_{\mathcal{F}}[l, k]$ , but  $Y_{\mathcal{S}}[l, k] \neq H_{\mathcal{S}}[l, k] * X_{\mathcal{S}}[l, k]$ . Nonetheless, as long as any result is first converted into the STFT domain (through Eq. (3)) before being used, it can still be employed to estimate the matrices and signals.

### 3. Signal and Array Model

Let there be a sensor array without any specific shape, which is comprised of  $M$  sensors, within a reverberant environment. In this setting there also are a desired and an interfering sources (name  $x[n]$  and  $v[n]$ ), and also uncorrelated noise,  $r_m[n]$  (at each sensor  $m$ ).

We denote  $h_m[n]$  as the room impulse response, between the desired signal (at source) and the  $m$ -th sensor. We similarly define  $g_m[n]$  for the interfering signal at source. From this, we write  $y_m[n]$  as the observed signal at the  $m$ -th sensor as

$$y_m[n] = h_m[n] * x[n] + g_m[n] * v[n] + r_m[n] \quad (4)$$

We let  $m'$  be the reference sensor's index (without compromise,  $m' = 1$ ). We let  $x_1[n] = h_1[n] * x[n]$  (and similarly for  $v_1[n]$ ).  $b_m[n]$  is the *relative* impulse response between the desired signal (at the reference sensor) and the  $m$ -th sensor, such that

$$b_m[n] * x_1[n] = h_m[n] * x[n] \quad (5)$$

and we similarly define  $c_m[n]$  such that  $c_m[n] * v_1[n] = g_m[n] * v[n]$ . Therefore, Eq. (4) becomes

$$y_m[n] = b_m[n] * x_1[n] + c_m[n] * v_1[n] + r_m[n] \quad (6)$$

We can use a time-frequency transform (in here the STFT or the SSBT, as exposed in Section 2) with the CTF model [8] to turn Eq. (6) into

$$Y_m[l, k] = B_m[l, k] * X_1[l, k] + C_m[l, k] * V_1[l, k] + R_m[l, k] \quad (7)$$

where  $Y_m[l, k]$  is the transform of  $y_m[n]$  (resp.  $B_m[l, k]$ ,  $X_1[l, k]$ ,  $C_m[l, k]$ ,  $V_1[l, k]$  and  $R_m[l, k]$ );  $l$  is the window index, and  $k$  the bin index, with  $0 \leq k \leq K - 1$ ; and the convolution is in the window-index axis.

Assuming that  $B_m[l, k]$  is a finite (possibly truncated) response with  $L_B$  windows, then

$$B_m[l, k] * X_1[l, k] = \mathbf{b}_m^T[k] \mathbf{x}_1[l, k] \quad (8)$$

in which

$$\mathbf{b}_m[k] = \left[ B_m[0, k], B_m[1, k], \dots, B_m[L_B - 1, k] \right]^T \quad (9a)$$

$$\mathbf{x}_1[l, k] = \left[ B_m[l, k], B_m[l - 1, k], \dots, B_m[l - L_B + 1, k] \right]^T \quad (9b)$$

and similarly we define  $\mathbf{c}_m[k]$  and  $\mathbf{v}_1[l, k]$ . Note that  $\mathbf{b}_m[k]$  doesn't depend on the index  $l$ , since the system is time-invariant. With this, Eq. (7) becomes

$$Y_m[l, k] = \mathbf{b}_m^T[k] \mathbf{x}_1[l, k] + \mathbf{c}_m^T[k] \mathbf{v}_1[l, k] + R_m[l, k] \quad (10)$$

Vectorizing the signals sensor-wise, we finally get

$$\mathbf{y}[l, k] = \mathbf{B}^T[k] \mathbf{x}_1[l, k] + \mathbf{C}^T[k] \mathbf{v}_1[l, k] + \mathbf{r}[l, k] \quad (11)$$

where

$$\mathbf{y}[l, k] = \begin{bmatrix} y_1[l, k], \dots, y_M[l, k] \end{bmatrix}^T \quad (12)$$

and similarly for the other variables. In this situation,  $\mathbf{B}[k]$  and  $\mathbf{C}[k]$  are  $L_B \times M$  and  $L_C \times M$  matrices respectively;  $\mathbf{x}_1[l, k]$  and  $\mathbf{v}_1[l, k]$  are  $L_B \times 1$  and  $L_C \times 1$  vectors respectively; and  $\mathbf{y}[l, k]$  and  $\mathbf{r}[l, k]$  are  $M \times 1$  vectors.

### 3.1. Reverb-aware formulation

We define  $\Delta$  as the window-index in which  $b_1[n]$  starts, and assume that  $b_1[n]$  starts at the start of a window of the transform<sup>1</sup>. We assume that the first window of  $\mathbf{B}[k]$  is the desired part of speech, and the rest is an undesired component, which is only reverberation.

With this, we write

$$\mathbf{B}^T[k] \mathbf{x}_1[l, k] = \mathbf{d}_x[k] X_1[l, k] + \sum_{\substack{l'=0 \\ l' \neq \Delta}}^{L_B-1} \mathbf{p}_{B,l'}[k] X_1[l - l', k] \quad (13)$$

where  $\mathbf{d}_x[k]$  is the  $k$ -th row of  $\mathbf{B}[k]$ , and  $\mathbf{p}_{B,l'}[k]$  is the  $l'$ -th row of  $\mathbf{B}[k]$ . With this,  $\mathbf{d}_x[k] X_1[l, k]$  is the desired speech component of  $\mathbf{B}^T[k] \mathbf{x}_1[l, k]$ , and the summation over  $l'$  is the undesired component. We will call  $\mathbf{d}_x[k]$  the desired speech frequency response.

We define  $\mathbf{p}_{C,l''}$  similarly, such that

$$\mathbf{C}^T[k] \mathbf{v}_1[l, k] = \sum_{l''=0}^{L_C-1} \mathbf{p}_{C,l''}[k] V_1[l - l'', k] \quad (14)$$

From here, we can write

$$\mathbf{y}[l, k] = \mathbf{d}_x[k] X_1[l, k] + \mathbf{w}[l, k] \quad (15)$$

with  $\mathbf{w}[l, k]$  being the undesired signal (undesired speech components + interfering source + noise), given by

$$\mathbf{w}[l, k] = \sum_{\substack{l'=0 \\ l' \neq \Delta}}^{L_B-1} \mathbf{p}_{B,l'}[k] X_1[l - l', k] + \sum_{l''=0}^{L_C-1} \mathbf{p}_{C,l''}[k] V_1[l - l'', k] + \mathbf{r}[l, k] \quad (16)$$

### 3.2. MVDR beamformer

We use a linear time-invariant filter  $\mathbf{f}[l, k]$  to estimate the desired signal at the reference sensor, such that

$$\begin{aligned} Z[l, k] &= \mathbf{f}^H[l, k] \mathbf{y}[l, k] \\ &\approx X_1[l, k] \end{aligned} \quad (17)$$

It is important to note that this filter is time-invariant within the window, but it may change over time depending on the signal.

<sup>1</sup> This can be easily achieved by left zero-padding all  $b_m[n]$  appropriately.

In order to minimize the undesired signal  $\mathbf{w}[l, k]$ , we will use an MVDR beamformer [10], whose formulation is

$$\mathbf{f}^*[l, k] = \min_{\mathbf{f}[l, k]} \mathbf{f}[l, k]^H \Phi_{\mathbf{w}}[l, k] \mathbf{f}[l, k] \text{ s.t. } \mathbf{f}^H[l, k] \mathbf{d}_x[k] = 1 \quad (18)$$

in which  $\mathbf{f}^H[l, k] \mathbf{d}_x[k] = 1$  is the distortionless constraint, and  $\Phi_{\mathbf{w}}[l, k]$  is the correlation matrix of the undesired signal, given by

$$\begin{aligned} \Phi_{\mathbf{w}}[l, k] = & \sum_{\substack{l'=0 \\ l' \neq \Delta}}^{L_B-1} \mathbf{p}_{B,l'}^H[k] \mathbf{p}_{B,l'}[k] \phi_{X_1}[l - l', k] \\ & + \sum_{l''=0}^{L_C-1} \mathbf{p}_{C,l''}^H[k] \mathbf{p}_{C,l''}[k] \phi_{V_1}[l - l'', k] \\ & + \mathbf{I}_M \phi_R[l, k] \end{aligned} \quad (19)$$

where  $\phi_{X_1}[l, k]$  is the variance of  $X_1[l, k]$  (same for  $\phi_{V_1}[l, k]$ ), and  $\mathbf{I}_M$  is the  $M \times M$  identity matrix, assuming that the distribution of  $\mathbf{r}[l, k]$  is the same for all sensors.

The solution to Eq. (18) is given by

$$\mathbf{f}_{\text{mvdr}}[l, k] = \frac{\Phi_{\mathbf{w}}^{-1}[l, k] \mathbf{d}_x[l, k]}{\mathbf{d}_x^H[l, k] \Phi_{\mathbf{w}}^{-1}[l, k] \mathbf{d}_x[l, k]} \quad (20)$$

Note that, even though overlapping windows are used when windowing the signal for the time-frequency transform, for simplicity we assume that  $X_1[l_1, k]$  is independent of  $X_1[l_2, k]$ .

#### 4. True-MVDR with the SSB Transform

In the formulation exposed previously, all signals and matrices are within the same domain. That is, in Eq. (18) we have that the distortionless constraint is built such that the beamformer doesn't cause distortion only on the SSBT domain. However, as was explained at the end of Section 2, since the filtering can't be done in the SSBT domain, the beamformer must be converted into the STFT domain (through Eq. (3)) before being applied to the signal. To correctly construct a beamformer that properly fulfills the distortionless constraint, this conversion should be taken into account.

Given the signal  $x[n]$ , its STFT  $X_{\mathcal{F}}[l, k]$  (with  $\left\lfloor \frac{K+1}{2} + 1 \right\rfloor$  bins), and its SSBT  $X_{\mathcal{S}}[l, k]$  (with  $K$  bins), from Eq. (3) it is possible to show that<sup>2</sup>

$$X_{\mathcal{F}}[l, k] = \frac{1}{\sqrt{2}} \left( e^{j\frac{3\pi}{4}} X_{\mathcal{S}}[l, k] + e^{-j\frac{3\pi}{4}} X_{\mathcal{S}}[l, K - k] \right) \quad (21)$$

From this, we propose a framework in which we consider both bins  $k$  and  $K - k$  simultaneously in the SSBT, given that they aren't independent. We thus define  $\mathbf{y}'[l, k]$  as

$$\mathbf{y}'[l, k] = \begin{bmatrix} \mathbf{y}[l, k] \\ \mathbf{y}[l, K - k] \end{bmatrix}_{2M \times 1} \quad (22)$$

<sup>2</sup> This equation (as well as the derivations going forward) is invalid for  $k = 0$ , and  $k = K/2$  if  $K$  is even. However, in those cases  $X_{\mathcal{F}}[l, k] = X_{\mathcal{S}}[l, k]$ , and the "naïve" SSBT beamformer works.

We similarly define  $\mathbf{v}'[l, k]$ , from which we define  $\Phi_{\mathbf{v}'}[l, k]$  as its correlation matrix. Under this idea, our filter  $\mathbf{f}'[l, k]$  is a  $2M \times 1$  vector, from which we can extract the SSBT beamformer  $\mathbf{f}[l, k]$  through

$$\mathbf{f}'[l, k] = \begin{bmatrix} \mathbf{f}[l, k] \\ \mathbf{f}[l, K - k] \end{bmatrix}_{2M \times 1} \quad (23)$$

with  $\mathbf{f}[l, k]$  being the beamformer for the  $k$ -th bin, and  $\mathbf{f}[l, K - k]$  for the  $[K - k]$ -th bin.

Defining  $\hat{\mathbf{A}}$  as

$$\hat{\mathbf{A}} = \begin{bmatrix} \frac{e^{j\frac{3\pi}{4}}}{\sqrt{2}} & 0 & \dots & 0 & \frac{e^{-j\frac{3\pi}{4}}}{\sqrt{2}} & 0 & \dots & 0 \\ 0 & \frac{e^{j\frac{3\pi}{4}}}{\sqrt{2}} & \dots & 0 & 0 & \frac{e^{-j\frac{3\pi}{4}}}{\sqrt{2}} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \dots & \frac{e^{j\frac{3\pi}{4}}}{\sqrt{2}} & 0 & 0 & \dots & \frac{e^{-j\frac{3\pi}{4}}}{\sqrt{2}} \end{bmatrix}_{M \times 2M} \quad (24)$$

then with Eq. (21) it is easy to see that

$$\hat{\mathbf{f}}_{\mathcal{F}}[l, k] = \hat{\mathbf{A}}\mathbf{f}'[l, k] \quad (25)$$

with  $\hat{\mathbf{f}}_{\mathcal{F}}[l, k]$  being the obtained beamformer, converted into the STFT domain. From this, the distortionless constraint for the STFT domain can be written for the SSBT domain as

$$\begin{aligned} \hat{\mathbf{f}}_{\mathcal{F}}^H[l, k]\mathbf{d}_{\mathcal{F};x}[k] &= 1 \\ \mathbf{f}'^H[l, k]\hat{\mathbf{A}}^H\mathbf{d}_{\mathcal{F};x}[k] &= 1 \\ \mathbf{f}'^H[l, k]\mathbf{D}_x[k] &= 1 \end{aligned} \quad (26)$$

where  $\mathbf{d}_{\mathcal{F};x}[l, k]$  is the desired speech frequency response in the STFT domain; and

$$\mathbf{D}_x[k] = \hat{\mathbf{A}}^H\mathbf{d}_{\mathcal{F};x}[k] \quad (27)$$

In this scheme, our minimization problem becomes

$$\mathbf{f}'^*[l, k] = \min_{\mathbf{f}'[l, k]} \mathbf{f}'^H[l, k]\Phi_{\mathbf{v}'}[l, k]\mathbf{f}'[l, k] \text{ s.t. } \mathbf{f}'^H[l, k]\mathbf{D}_x[k] = 1 \quad (28)$$

#### 4.1. Real-valued SSBT true-MVDR beamformer

Given that  $\mathbf{D}_x$  is a complex-valued matrix, the solution to Eq. (28) will generally be complex as well, which defeats the purpose of using the SSBT, given that its spectrum is real-valued. Thus, another restriction must be added in order to ensure this desired behavior.

From the distortionless constraint of Eq. (28), we trivially have that

$$\mathbf{f}'^H[l, k]\Re\{\mathbf{D}_x[k]\} = 1 \quad (29a)$$

$$\mathbf{f}'^H[l, k]\Im\{\mathbf{D}_x[k]\} = 0 \quad (29b)$$

which can be put in matricial form,

$$\mathbf{f}'^H[l, k]\mathbf{Q}_x[k] = \mathbf{i}^T \quad (30)$$

with

$$\mathbf{Q}_x[k] = \begin{bmatrix} \Re\{\mathbf{D}_x[k]\} & \Im\{\mathbf{D}_x[k]\} \end{bmatrix}_{2M \times 2} \quad (31a)$$

$$\mathbf{i} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \quad (31b)$$

From this, the minimization problem becomes

$$\mathbf{f}'^*[l, k] = \min_{\mathbf{f}'[l, k]} \mathbf{f}'^H[l, k] \Phi_{\mathbf{v}'}[l, k] \mathbf{f}'[l, k] \text{ s.t. } \mathbf{f}'^H[l, k] \mathbf{Q}_x[k] = \mathbf{i}^T \quad (32)$$

whose formulation is the same as the linearly-constrained minimum variance (LCMV) [14] beamformer, and therefore its solution is

$$\mathbf{f}'^*[l, k] = \Phi_{\mathbf{v}'}^{-1}[l, k] \mathbf{Q}_x[k] \left( \mathbf{Q}_x^H[k] \Phi_{\mathbf{v}'}^{-1}[k] \mathbf{Q}_x[k] \right)^{-1} \mathbf{i} \quad (33)$$

Since all matrices involved in the calculation of this beamformer are now real-valued, then it is trivial that

$$\mathbf{f}'_{\text{mvdr}}^*[l, k] = \Phi_{\mathbf{v}'}^{-1}[l, k] \mathbf{Q}_x[k] \left( \mathbf{Q}_x^T[k] \Phi_{\mathbf{v}'}^{-1}[k] \mathbf{Q}_x[k] \right)^{-1} \mathbf{i} \quad (34)$$

and, using Eq. (25), we can obtain the desired beamformer  $\hat{\mathbf{f}}_{\mathcal{F}}^*[l, k]$ , in the STFT domain.

## 5. Simulations

In the simulations<sup>3</sup>, we will use a sampling frequency  $f_s = 16\text{kHz}$ . The sensor array is assumed an uniform linear array of 10 sensors, with an intersensor distance of 2cm. All RIR's were generated using Habets' room impulse generator [15]. Signals used were from the SMARD [16] and LINSE [17] databases.

The room's dimensions are  $4\text{m} \times 6\text{m} \times 3\text{m}$ , with a reverberation time of 0.11s. The desired source is located at (2m, 1m, 1m), and its signal is a male voice (SMARD, 50\_male\_speech\_english\_ch8\_OmniPower4296.flac).

The interfering source is located (simultaneously) at (0.5m, 5m, [0.3 : 0.3 : 2.7]m), emulating an open door, with its signal being a babble sound (LINSE database, babble.mat). The noise signal is a WGN noise (SMARD database, wgn\_48kHz\_ch8\_OmniPower4296.flac). All signals were resampled to the desired sampling frequency. The sensor array is assumed to be an uniform linear array, positioned at (2m, [4.02 : 0.02 : 4.2]m, 1m), whose sensors are assumed to be omnidirectional and with flat frequency response.

We have that the input SNR between desired and interfering signals is of 5dB, and the SNR between desired and noise signals is of 30dB. The filters were calculated every 25 windows, and consider the previous 25 windows, in order to calculate the correlation matrices.

We will compare the filters obtained through the STFT and SSBT transforms, with T-SSBT denoting the beamformer obtained via the true-distortionless MVDR derived in Section 4, and N-SSBT the naïve approach, in which one would simply use Eq. (20) to calculate the SSBT beamformer. The performance analysis was done only on the STFT

<sup>3</sup> The code for the simulations can be found in <https://github.com/VCurtarelli/py-ssb-ctf-bf>.

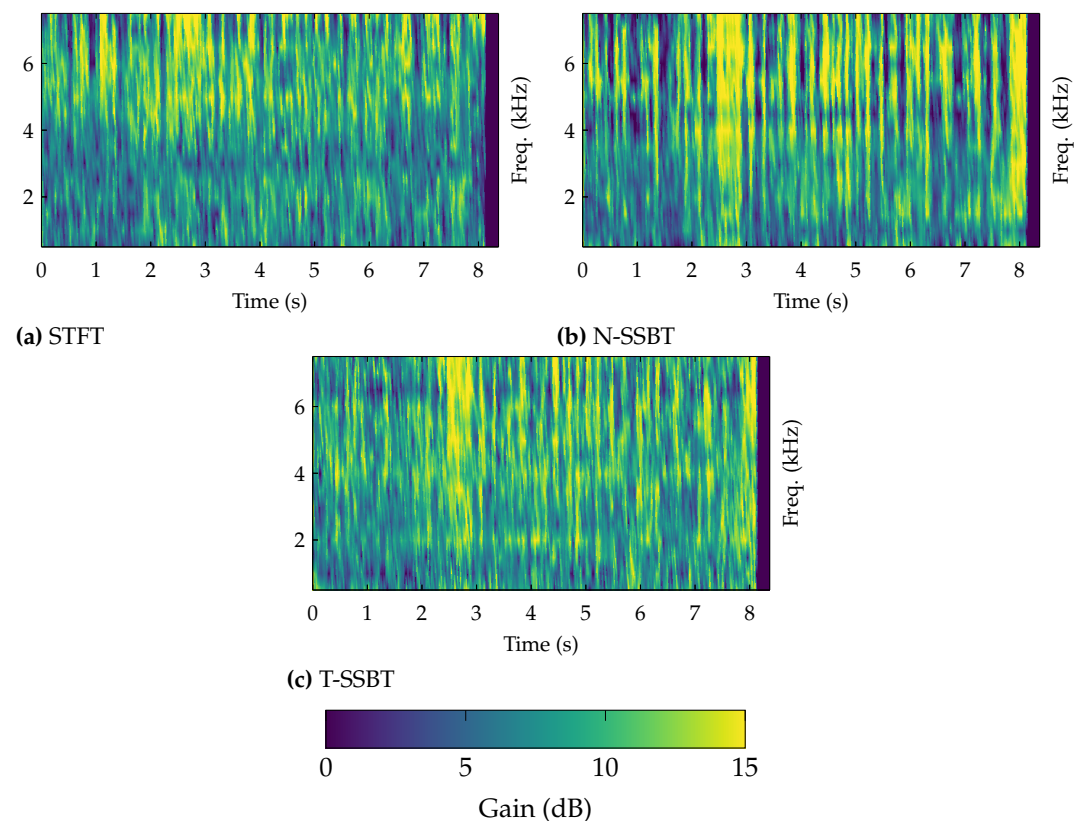

domain. In all lineplots, the STFT is presented in red, the N-SSBT in green, and the T-SSBT in blue.

### 5.1. Results

In this scenario, we assume that the analysis (and synthesis) windows have 32 samples. Figure 2 shows the window-wise averaged gain in SNR, and Fig. 1 the gain in SNR for each window (with the windows being represented by the time started, in seconds), for all methods. In Fig. 3 we have the DSDI for all three methods, window-averaged.

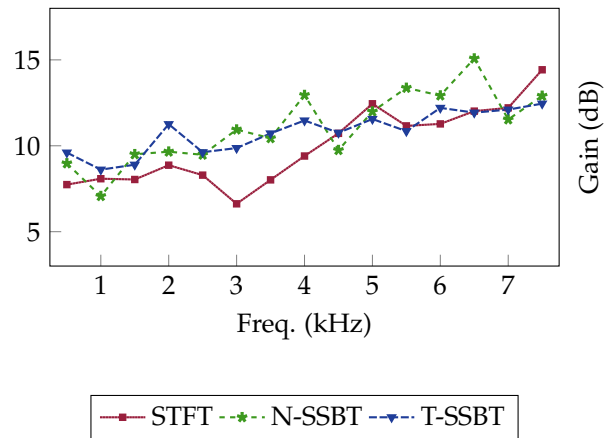

Although it isn't as clear from the per-window results of Fig. 1, Fig. 2 shows us that both beamformers obtained from the SSBT led to a better enhancement of the signal, in terms of the output SNR, with the N-SSBT beamformer having a better performance over (almost) all spectrum, and the T-SSBT beamformer being better for lower frequencies, tying with the STFT for higher ones.

Also, Fig. 3 shows that the T-SSBT filter was able to ensure a distortionless response for the desired signal, a feature that wasn't achieved by the N-SSBT beamformer. This is wholly expected, since the later was naively designed with the MVDR in mind, and wasn't fully planned to achieve a distortionless behavior in the STFT (and therefore the time) domain, while the T-SSBT took this into account on its derivation.

**Figure 1.** Per-window SNR gain.

**Figure 2.** Window-average SNR gain.

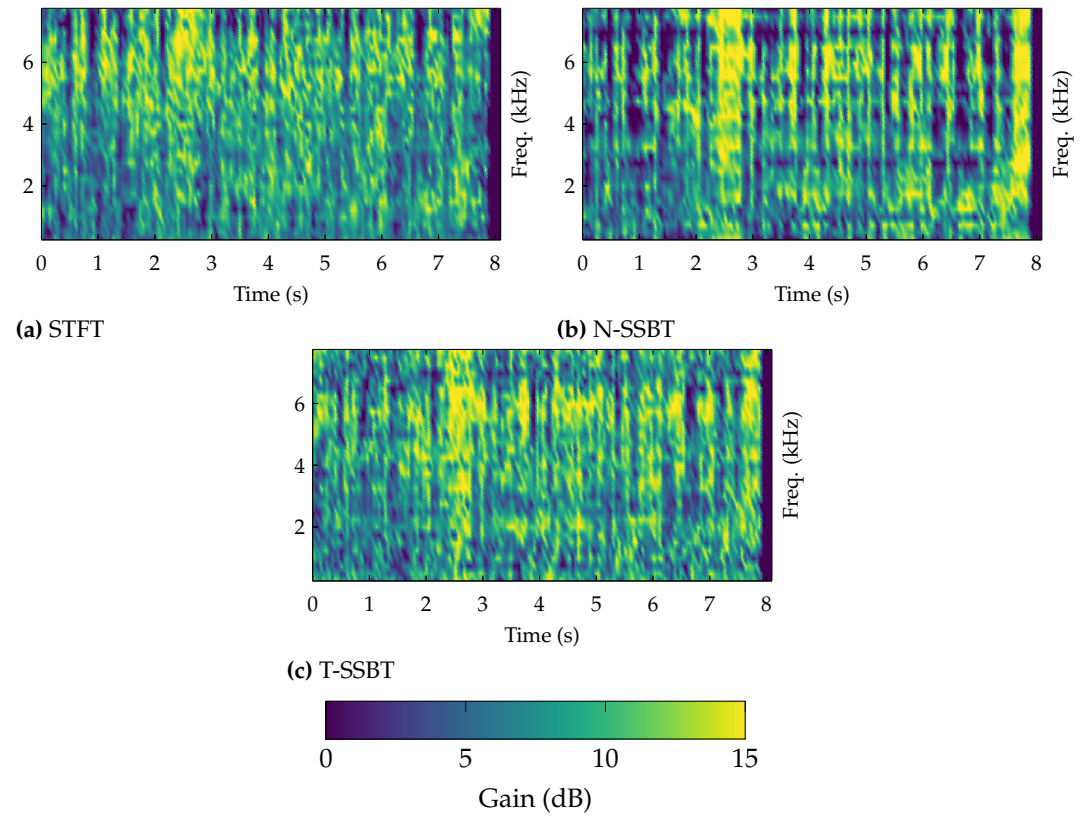

**Figure 3.** Window-average DSDI.

## 5.2. Results - 64 samples/window

In this simulation, we changed the number of samples per window from 32 to 64, keeping everything else the same.

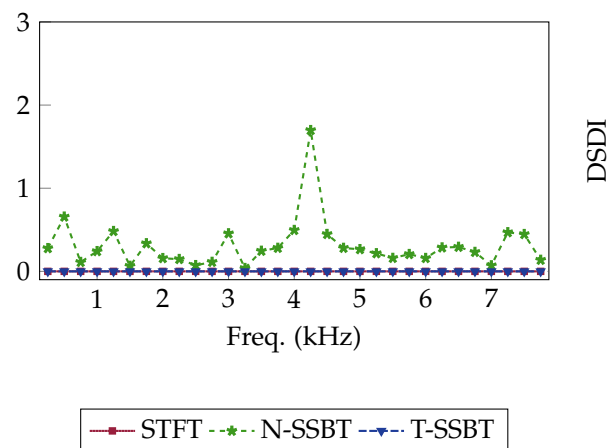

In here, from Figs. 4 and 5 we see a similar result to that which was obtained previously, with the N-SSBT beamformer having a better performance overall, but causing some distortion in the desired signal; while the T-SSBT beamformer has a slightly better performance than the one obtained through the STFT, while also having a distortionless behavior, as is seen in Fig. 6.

**Figure 4.** Per-window SNR gain.

**Figure 5.** Window-average SNR gain.

**Figure 6.** Window-average DSDI.

## 6. Conclusion

In this study, we explored the use of the single-sideband transform for beamforming in a reverberant environment, using the CTF frequency model for calculating filter banks (that is, the beamformer). We employed an MVDR beamformer to enhance the signals obtained via a real-life-like situation, and detailed the process to obtain a true-distortionless MVDR beamformer when using the SSB transform. The results obtained showed that both the naive MVDR and the true MVDR beamformers obtained through the SSB outperformed the one obtained using the traditional STFT, with the naive MVDR having some distortion on the desired signal, given its formulation, while the true-MVDR obtained a distortionless response, as expected.

Cohen and V. Curtarelli; Supervision, V. Curtarelli. All authors have read and agreed to the published version of the manuscript.

**Funding:** This research was supported by the Pazy Research Foundation, and the Israel Science Foundation (grant no. 1449/23).

**Data Availability Statement:** The source-code for the simulations developed here is available at <https://github.com/VCurtarelli/py-ssb-ctf-bf>.

**Conflicts of Interest:** The authors declare no conflict of interest.

## Abbreviations

The following abbreviations are used in this manuscript:

STFT	Short-Time Fourier Transform
SSBT	Single-Sideband Transform
CTF	Convolutional Transfer Function
MVDR	Minimum-Variance Distortionless-Response
LCMV	Linearly-Constrained Minimum-Variance
